Executive Summary: Revenue Forecasting and Price Sensitivity

Revenue is driven by network size, not price.
Annual revenue grew from £1.03M (2022) to £2.59M (2023) to £4.55M (2024), tracking the station count (8,17,33). Per-station demand was essentially flat at about 13.9 stations per station-day through both price changes (+ 25% in 2023, -8% in 2024).

No price sensitivity could be detected.
Year-level elasticity estimates were -0.21 and +0.21, with opposite signs and too small a value. At the session level, the remaining price variation after removing year and peak-hour effects correlated about -0.002 with energy per session. The dataset also looks simulated, so this result may reflect how it was generated, not how real customers behave.

2025 baseline forecast:
The baseline was £4.50M, assuming 33 stations and the 2024 average price (£0.588/kWh). The demand model was validated at 3.8% daily error on a held-out 90-day set. This is strong weekly seasonality (weekends about 27% lower) but no reliable yearly seasonality.

Price scenarios
At the measured elasticity (about zero), a 5% price rise adds 5.0% to revenue (£4.73M); about a 10% cut loses 10.0% (£4.05M). The break-even elasticity is -1. Below it, price rises lose money. At -15, a 5% rise would cost 2.4% and a 10% cut would gain 5.4%. These figures are a sensitivity analysis because the data cannot say which side of -1 real customers fall on.

Implication
On this evidence, a modest price rise is low-risk, but the evidence is thin (three yearly price levels). A staged pilot at a subset of stations would test real behavior before a network-wide change. The larger lever is network growth, with each station worth about £136k a year at baseline.
